## SUMMARY

The performance of a Lycoming YF-102 turbofan engine was measured in an outdoor test stand with a bellmouth inlet and seven exhaust-system configurations. The configurations consisted of three separate-flow systems of various fan and core nozzle sizes and four confluent-flow systems of various nozzle sizes and shapes. A Lycoming computer program provided good estimates of the engine performance and of thrust at maximum rating for each exhaust configuration. The internal performance of two different-shaped core nozzles for confluent-flow configurations was determined to be satisfactory. Pressure and temperature surveys were made with a traversing probe in the exhaust-nozzle flow for some confluent-flow configurations. The survey data at the mixing plane, plus the measured flow rates, were used to calculate the static-pressure variation along the exhaust-nozzle length. The computed pressures compared well with experimental wall static-pressure data. External-flow surveys were made, for some confluent-flow configurations, with a large fixed rake at various locations in the exhaust plume.

## INTRODUCTION

As part of the NASA Quiet Short-Haul Research Aircraft (QSRA) Project, an airplane using the upper-surface-blown propulsive lift concept has been built. The airplane is shown in figure 1. Its purpose is to conduct flight research into takeoff, approach, and landing problems. The airplane and its preliminary performance characteristics are described in references 1 and 2.

The QSRA is powered by four YF-102 engines manufactured by AVCO Corp. Lycoming Division, Stratford, Connecticut. The engines were built for use on the Northrup A-9A aircraft. At the conclusion of the A-9A program at Edwards Air Force Base, the YF-102 engines were obtained by NASA. Five of the engines were refurbished at the factory for use on QSRA. At the same time, some configuration changes (including addition of a core airbleed manifold) were made, as described in reference 3. One of these engines was sent to the NASA Lewis Research Center to be used in obtaining test data for designing the QSRA propulsion system and noise suppression treatment.

The NASA Lewis test program was planned to measure both the acoustic characteristics and the aerodynamic performance of the engine. The results of some of these tests are reported in references 4 to 6. The tests that assess the steady-state aerody-

namic engine performance (for no airbleed or power extraction) are reported herein. Other tests, not reported, included engine acceleration and deceleration tests with core airbleed up to 14 percent of the core inlet airflow. The objectives of the steady-state tests were as follows:

- (1) To gain NASA experience with engine performance and characteristics
- (2) To test the engine with confluent-flow exhaust systems (few data were then available)
- (3) To compare the measured performance with the performance estimated by the Lycoming engine-simulation computer program
- (4) To provide design information for the QSRA

At the time the NASA Lewis test program was begun, the final QSRA configuration had not yet been determined. Consequently, both separate-flow and confluent-flow exhaust systems were tested. For convenience, economy, and ease in comparing results, the exhaust-system hardware was made up of simple round shapes that had effective flow areas in the range of interest for QSRA. All tests were performed with a bell-mouth inlet on an outdoor static test stand. Engine performance parameters were measured over a full range of power settings. Flow surveys were made inside the engine and in the jet exhaust plume. Data are presented in graphs and tables.

## APPARATUS

### Engine

The Lycoming YF-102 engine (complete designation YF-102-LD-100 (QSRA updated), Lycoming Model ALF 502A) is a twin-spool turbofan powerplant. Illustrative sketches of the engine are shown in figure 2. The core engine consists of a combination seven-stage axial and single-stage centrifugal compressor driven by a two-stage axial turbine and an external atomizing combustor. An interstage bleed valve (ISBV) vents air from the sixth axial compressor stage, as required, to prevent compressor stall. This valve is open at low power settings and during rapid thrust transients and is automatically closed by a schedule in the fuel control. The front fan and one supercharging stage are driven by a two-stage, free coaxial power turbine through a 2.3-to-1 speed-reducing gear system. Maximum rating performance at sea-level static conditions with ideal inlet and exhaust systems is 33 360 newtons (7500 lb) thrust (minimum), 7600 rpm fan speed (maximum), and 6.2 bypass ratio (nominal). Maximum rating is defined by the manufacturer as the performance at 1194 K (1690° F) measured gas temperature (MGT) or at any of several other defined mechanical limits during off-design operation. The MGT is the average temperature sensed by 10 thermocouples spaced throughout the flow passage at the power turbine inlet.

## Inlet System

The air inlet system used for all tests, shown in figures 3 and 4, consisted of a bellmouth and a transition section supported from the test stand and connected to the engine by a flexible joint. The bellmouth, previously used in another test program, was 193 centimeters (76 in.) in diameter at the inlet and had a straight exit section 112 centimeters (44 in.) in diameter. The transition section reduced the airflow passage to 101.6 centimeters (40 in.), the diameter of the engine inlet. The flexible joint included a soft neoprene seal and prevented transfer of large inlet system loads to the engine.

## Separate-Flow Exhaust Systems

The separate-flow exhaust systems used for these tests (fig. 3) consisted of a core cowling, a core engine nozzle, and a fan nozzle. The core cowling was the same as that used on the A-9A airplane, except that it was shortened 13 centimeters (5 in.) for certain acoustic tests. The cowling was made of stainless-steel skin and frames and was mounted in cantilever fashion from a lip on the core engine.

The basic core nozzle was also the same as that used on the A-9A airplane. It consisted of a conical steel shell with a short straight section at the exit. A centerbody was attached to the shell by six flow-straightening vanes. The nozzle had a geometric exit area of 1361 square centimeters ( $210.9 \text{ in}^2$ ). For the smaller-core-nozzle configuration, the basic nozzle was made smaller by adding a conical insert at the aft end. The smaller nozzle had a geometric exit area of 1163 square centimeters ( $180.2 \text{ in}^2$ ).

The basic fan nozzle was a conical shell mounted from an engine flange aft of the frame assembly. The diameter of the basic nozzle was 99.9 centimeters (39.3 in.), which provided a geometric annular flow area of 3640 square centimeters ( $564 \text{ in}^2$ ). The smaller fan nozzle had the same wall angle as the basic nozzle but was 96.5 centimeters (38.0 in.) in diameter. The smaller fan nozzle provided 3230 square centimeters ( $500 \text{ in}^2$ ) of geometric annular flow area.

The basic separate-flow configuration (S-1) used the basic fan and core nozzles. These nozzles were approximately the sizes recommended by Lycoming for QSRA if the final design used a separate-flow exhaust system.

## Confluent-Flow Exhaust Systems

The confluent-flow exhaust systems used for these tests (fig. 4) consisted of a core cowling, a core-engine nozzle, and a bypass-flow duct ending in an exhaust nozzle for the combined fan and core flows. The two configurations that used the same core nozzle are shown in figure 4(a). The core cowling was the same as that used for the separate-

flow configurations, except that small scoops were installed over the existing ventilation ports at the forward end to force air into the engine space. Also, a 33-centimeter-(13-in.-) long aft skirt was added to the cowling to smooth the flow passage over the core nozzle.

The core nozzle is intended to diffuse the core flow in order to produce a satisfactory static-pressure match with the bypass flow at the mixing plane. To this end the basic nozzle consisted of a divergent cone attached to the shell of an A-9A core nozzle downstream of the straightening vanes. Although this resulted in a long nozzle, it was simple to fabricate and was expected to be aerodynamically successful because the flow would be fairly uniform before it began to diffuse. The exit diameter was 46.35 centimeters (18.25 in.), and the geometric exit area was 1687 square centimeters ( $261.5 \text{ in}^2$ ). The bypass-flow duct was made of steel extension and adapter spools and included a flexible joint near the engine mounting flange. The basic exhaust nozzle had a diameter of 78.2 centimeters (30.79 in.), which provided a geometric flow area of 4803 square centimeters ( $744.4 \text{ in}^2$ ). The geometric flow area in the bypass duct at the mixing plane was 4451 square centimeters ( $689.9 \text{ in}^2$ ).

The basic confluent-flow configuration (C-1) used the basic core and exhaust nozzles assembled as shown in figure 4(a). The nozzle areas, bypass-flow-duct area, and mixing length were approximately the same as those used for QSRA performance estimates if the final design used a confluent-flow exhaust system.

The larger exhaust nozzle, also shown in figure 4(a), had the same wall angle as the basic exhaust nozzle but had an exit diameter of 83.22 centimeters (32.80 in.), which provided a geometric flow area of 5453 square centimeters ( $845.2 \text{ in}^2$ ). The mixing length of this nozzle was only about half the mixing length of the basic nozzle.

The other confluent-flow configurations tested are shown in figure 4(b). The core cowling was the same as that for the configurations in figure 4(a), except that the aft skirt was not used. Two core nozzles are shown. The smaller core nozzle was the same as the basic core nozzle for the separate-flow configurations. The other nozzle was a short design intended to perform the same as the basic core nozzle. This nozzle consisted of a divergent conical outer steel shell with the straightening vanes and centerbody from the A-9A nozzle. The vanes were extended on both the inner and outer ends as required to mate to the new shell. The extensions were shaped and contoured by extrapolating the existing vane shape to the new radial length. No flow analyses were made to optimize the new vane contour. This nozzle had an exit diameter of 47.23 centimeters (18.59 in.), which provided a geometric flow area of 1752 square centimeters ( $271.5 \text{ in}^2$ ).

For the configurations shown in figure 4(b), the bypass-flow duct was the same as that in the basic confluent-flow configuration, except that a shorter adapter was used to

give the same mixing length. Mixing-plane geometric flow areas and other pertinent information are included in the figure.

### Instrumentation and Data Processing

The instrumentation used to measure engine steady-state performance is summarized in table I. The raw data for each test reading consisted of two scans of the complete instrument list. Most of the instrumentation was sampled once per scan (scan duration,  $\sim 15$  sec), but net thrust and fan speed were sampled many times to obtain better average values. The raw data were recorded on the Lewis central data system and processed on a digital computer with a program specially written for these tests. The program averaged and listed the data; corrected results to standard-day temperature and pressure; and computed airflows, nozzle coefficients, and other performance parameters. The parameters used throughout this report are summarized in the appendix.

For some tests with the confluent-flow configurations, flow surveys were made with a traversing probe mounted from the bypass-flow duct either at the mixing plane (station 16) or at station 18. At either station, the probe could be located at the  $90^\circ$  or  $135^\circ$  circumferential position (aft, facing forward). The probe is shown in figure 5(a), and details of the pressure- and temperature-sensing elements are given in figure 5(b). Data from the probe, plus fan speed and probe position, were recorded while the probe was traversed slowly from the wall to the engine centerline and back to the wall again. The data were processed by a NASA Lewis computer program that collected data into "bins" spaced 0.64 centimeter (0.25 in.) apart, averaged like measurements in each bin, and then computed flow parameters from the averaged data. Fan speed was the grand average of all the fan speed measurements made during the whole traverse.

For some tests with the confluent-flow configurations, jet plume data were obtained with "super-rake." Super-rake is a large rake containing total-pressure, static-pressure, and total-temperature sensing elements mounted horizontally from a cart at a specified distance behind the engine. The super-rake on the mounting cart and in position for testing is shown in figures 6(a) and (b), and a schematic sketch of the rake is shown in figure 6(c). The data were processed by a NASA Lewis computer program, which averaged two scans of data at each super-rake station and then computed flow parameters from the averaged data.

At various places in this report, the data are identified by reading number. A typical identification is "007/045." The first number refers to the data-processing computer program, and the number after the slash mark identifies a particular data set. The computer program numbers are as follows:

Program 007 - Engine steady-state performance

Program 008 - Engine steady-state performance for acoustic tests

Program 009 - Traversing probe

Program 010 - Super-rake

Program 008 was a shortened version of 007 that accounted for removal of some instrumentation rakes for the acoustic tests.

### Test Facility

All tests were conducted at the Vertical Lift Fan (VLF) Facility at the NASA Lewis Research Center. This facility is an outdoor, static engine test stand sheltered by a service building that is moved away on tracks before testing begins. The engine is shown ready for testing in figure 7. The engine was suspended beneath the thrust-measuring system, which can be pivoted around a vertical axis for operational convenience. Frameworks extending from the thrust-measuring system were used to mount inlet and exhaust ducts and other hardware separately from the engine. The engine centerline was 2.9 meters (9.5 ft) above the ground. The control room was about 150 meters (500 ft) from the engine.

### PROCEDURE

For each configuration, the engine was run over a range of power settings from idle to as near 1194 K (1690° F) measured gas temperature (MGT) as feasible. Thus, the measured maximum performance depended on the ambient pressure and temperature at test time as well as on the configuration. All performance parameters have been corrected (or "referred") to standard-day ambient conditions so that valid comparisons can be made.

At preselected, corrected fan speeds, the engine was allowed to "steady out" for 2 minutes or longer. Data were taken when fan speed, which was affected by wind gusts and direction changes, was reasonably steady, as indicated by a strip-chart recorder in the control room. For all data, the wind speed was less than 3.6 meters per second (8 mph). The aerodynamic performance tests were intermixed with acoustic and other tests (e.g., tests reported in refs. 4 and 5). For many configurations and power settings the data were repeated so that different super-rake positions, traverses, etc., could be obtained at approximately the same fan speed.

## RESULTS AND DISCUSSION

### Method of Presentation

Experimental data. - All the important test results are listed in tables II to XIII. Typical results are also shown in graphical form and discussed in the text. The graphs were plotted from information in the tables. Measured and computed parameters, along with units, are summarized and defined in the appendix.

The engine with the basic confluent-flow configuration (C-1) was chosen as the baseline configuration. In this report, the performance of the engine with the other exhaust-system configurations generally is compared with this baseline.

Lycoming computer program. - For each configuration, the experimental performance is compared with the steady-state performance estimated for the same configuration by AVCO Lycoming program 10.12.113.25. This is an engine synthesis computer program usable for a large variety of inlet and exhaust systems over a wide range of flight conditions. The turbomachinery maps in the program were modified slightly from the standard model ALF 502 maps so they would represent more accurately the known performance of the particular engine used for these tests. Program input was as follows:

- (1) Standard-day atmosphere:  $10.132 \text{ N/cm}^2$  ( $14.696 \text{ lb/in}^2$ ) and  $288.2 \text{ K}$  ( $518.7^\circ \text{ R}$ )
- (2) No inlet losses
- (3) No power extraction or external airbleeds
- (4) One-percent total-pressure loss in the bypass-flow duct, for confluent-flow configurations only. (This loss input adds to the duct loss (internally programmed) that occurs between the fan and the fan-nozzle mounting flange.)
- (5) Effective flow areas and/or exhaust-system performance coefficients determined in the NASA Lewis test of that same configuration

The program output is a listing of the estimated performance at power settings from idle to maximum rating. Maximum rating is determined by reaching  $1194 \text{ K}$  ( $1690^\circ \text{ F}$ ) MGT or by encountering any of several internally programmed mechanical limits for off-design operation. The program indicates when the interstage bleed valve (ISBV) is open but does not define a power setting at which it just begins to close.

### Engine Performance

No serious mechanical problems or unusual operating behavior were encountered with the engine during this test program.

Basic confluent-flow configuration. - The performance of the engine with the basic confluent-flow configuration (C-1) is given in table II and in figures 8 to 16.

The variation of corrected thrust with corrected fan speed is shown in figure 8. The repeatability of the experimental data, which were taken on different test days, is very good. A dot-dashed line has been faired through the experimental data and is used herein as a baseline for comparison with the other configurations tested. The computer program provides a good estimate of the performance as shown by the dashed line in the figure. The largest difference between measured and estimated thrust, about 400 newtons (90 lb), occurred near maximum fan speed. The closure of the ISBV was not measured, but there is no reason to believe that it did not operate correctly within the predicted speed range.

The relation between corrected thrust and corrected MGT is shown in figure 9. The correction factor,  $1/(\theta 1)^{1.022}$ , is recommended by Lycoming. The estimated MGT was reasonably accurate at high power settings, but it tended to be greater than measured values at lower power settings. The thrust at the maximum performance rating for this configuration and for all the other configurations tested is discussed near the end of this section, Engine Performance.

The variation of corrected core-compressor speed with corrected fan speed is shown in figure 10. This graph shows that the estimated core speed was accurate, except near maximum power.

The corrected inlet airflow and the bypass ratio are shown as a function of corrected fan speed in figures 11 and 12, respectively. The measured airflow tended to be a little less than the nominal estimate but well within the  $\pm 3$ -percent allowable tolerance, except near idle power setting. The bypass ratio estimate was accurate at all power settings.

The measured total-pressure loss in the bypass-flow duct is shown in figure 13. Data from the other confluent-flow configurations tested are also included. The results seem to generalize well; the scatter was probably caused by configuration differences and the difficulty in measuring the average station-16 pressure accurately. (Only two fixed instrumentation rakes were used; see table I.) The pressure loss indicated by these results was approximated by the 1-percent total-pressure loss in the bypass-flow duct that was input to the Lycoming computer program.

The variation in corrected mixing-plane static pressure with corrected fan speed is shown in figure 14. The data plotted in this figure are a weighted average from station-6 and station-16 static-pressure instrumentation (table I). The data are in good agreement with the computer estimates, even though the static pressure measured during traverses varied throughout the mixing plane, as shown in detail in the section Internal-Flow Survey.

Figure 15 shows the free-skin temperature at various locations on the core cowling. The cowling skin was made from 0.081-centimeter- (0.032-in.-) thick 321 stainless

steel. The increase in temperature at low fan speed was caused by the warm air vented under the cowling by the normal action of the ISBV.

As shown in figure 16, two of the six ventilating air scoops on the core cowling were specially instrumented with total-pressure sensing tubes. Although each scoop was in the wake of a strut on the fan frame, the pressure of the air entering the scoops was always greater than 92 percent of the fan discharge pressure.

Shorter-core-nozzle confluent-flow configuration. - Performance of the shorter-core-nozzle confluent-flow configuration (C-4) is given in table III and in figures 17 to 20. This configuration was designed to make the overall exhaust system shorter than the basic configuration while maintaining the same performance.

The variation of corrected thrust with corrected fan speed is shown in figure 17. The performance was almost identical to that of the basic configuration (dot-dashed line). The computer program provided a good estimate of the performance, as expected, because the flow areas and other program inputs were almost the same.

The similarity in performance with the basic confluent-flow configuration indicates that the basic and shorter-core-nozzle flow characteristics were essentially the same. As a further indication, the wall static pressures measured along the length of each nozzle are shown in figure 18. The data are presented as the ratio of wall pressure to measured total pressure at station 5 for various corrected fan speeds. They are plotted against nozzle geometric flow area in the plane containing the static-pressure tap. Similar station-5 rakes were used in both nozzles. For each nozzle, the wall pressures increased in the flow direction to the exit (except near the six vanes holding the center-body). Separation would cause the measured wall pressure to become constant downstream of the separation point. Thus, no flow separation occurred in either nozzle, and the desired flow diffusion and static-pressure rise took place effectively.

The total pressure at the exits of the same two nozzles is given in figure 19. Data are presented as the ratio of the measured pressures at stations 6 and 5 and are shown as a function of corrected fan speed. The station-6 data were obtained during mixing-plane flow surveys, from which the area-weighted average total pressures were computed for this figure. The station-5 data were obtained from fixed rakes. However, the flow passages were not identical in the two nozzles forward of station 5, so the total-pressure losses (not measured in these tests) from the inlet to station 5 could be different. Hence, no direct comparison of losses for the whole nozzles can be made. On the basis of the data available, up to 2.5 percent loss was measured at high power setting. The basic nozzle appeared to have the greater loss, probably because of its longer length.

The corrected thrust specific fuel consumption for the shorter-core-nozzle confluent-flow configuration (C-4) is shown in figure 20. The shape of the curve is conventional. The best performance was attained at 20 000 newtons (4500 lb) corrected

thrust and is 0.0105 g fuel/sec N thrust (0.37 lb fuel/hp lb thrust). The computer program estimates the performance very well at all power settings when the ISBV is closed. This is the only configuration for which a full set of reliable fuel-flow data were obtained.

Other confluent-flow configurations. - The performances of the larger-exhaust-nozzle confluent-flow configuration (C-5) and the smaller-core-nozzle confluent-flow configuration (C-6) are given in tables IV and V and figures 21 and 22, respectively. The corrected thrust for the larger exhaust nozzle, shown as a function of corrected fan speed in the figure, was significantly less than that for the basic confluent-flow configuration (C-1). The corrected thrust for the smaller core nozzle was a little better than that for the basic configuration. The computer program showed trends and estimated the performance reasonably well for both configurations.

Separate-flow configurations. - The performances of the basic separate-flow configuration (S-1), the smaller-core-nozzle separate-flow configuration (S-3), and the smaller-fan-nozzle separate-flow configuration (S-4) are given in tables VI to VIII and figures 23 to 25, respectively. As shown in the figures, for each configuration the corrected thrust at a given corrected fan speed was the same or slightly less than that for the basic confluent-flow configuration (C-1). The computer program predicted the direction of these trends but did not always accurately predict the magnitude of the changes. The largest difference between measured and estimated thrust occurred near maximum fan speed for separate-flow configurations S-1 and S-3; for each, the difference was 900 newtons (200 lb).

Thrust at maximum performance rating. - For the YF-102 engine the maximum rating is defined as the performance at 1194 K (2150° R, 1690° F) MGT or at some other limiting mechanical condition in the engine if that condition is reached at lesser MGT. For each configuration tested, the thrust at maximum rating for standard-day static conditions was determined by plotting corrected measured thrust against corrected measured MGT and reading the curve faired through these data at 1194 K corrected MGT (extrapolating, if necessary). Fan speed at maximum rating was found in a similar manner by plotting corrected fan speed against corrected MGT.

The experimental and estimated thrusts at maximum rating for standard-day static conditions for all the configurations tested are compared in figure 26. On this basis, the basic separate-flow configuration (S-1) produced the most thrust. The larger-exhaust-nozzle confluent-flow configuration (C-5) was next best, but that maximum thrust could be attained only on cold days because limiting mechanical fan speed was 7600 rpm. The smaller-fan-nozzle separate-flow configuration (S-4) had the next best performance; it provided about 300 newtons (70 lb) more thrust than the basic confluent-flow configuration. The differences in engine performance are attributed to changes in the core-fan speed match line caused by nozzle area changes as well as by differences

in exhaust-system performance. The range of speed match covered in these tests is shown in figure 27. For the same fan speed, the core speed was lowest for the larger-exhaust-nozzle confluent-flow configuration (C-5) and was highest for the smaller-core-nozzle confluent-flow configuration (C-6).

It must be emphasized that the comparisons discussed herein refer to standard-day static performance only, since only outdoor test-stand data were obtained. The choice of an exhaust system for a particular application would be based on the performance at pertinent flight conditions and altitudes, as well as on ground performance.

### Internal-Flow Survey

Internal-flow surveys were made with fixed rakes at station 13.2 and with a traversing probe at the mixing plane (station 16) and at station 18 for some of the confluent-flow configurations. The data are given in tables IX to XI and in figures 28 to 30. An index of the tabulated data is as follows:

Confluent-flow configuration	Table	Data taken at stations	Approximate fan speed, rpm
Basic (C-1)	IX(a), (b), (c)	13.2, 16, 18	3810
	IX(d), (e), (f)	13.2, 16, 18	4580
	IX(g), (h), (i)	13.2, 16, 18	5730
	IX(j), (k), (l)	13.2, 16, 18	7260
Shorter core nozzle (C-4)	X(a), (b), (c), (d)	16	3660, 4410, 5500, 6960
Larger exhaust nozzle (C-5)	XI(a), (b), (c)	18	4570, 6460, 7610

In these tables, available data have been averaged, where deemed appropriate, to show the most meaningful results. Thus, at stations 16 and 18, data from traverse surveys at  $90^{\circ}$  and  $135^{\circ}$  circumferential positions have been averaged for the tables, except where noted.

Typical flow-velocity data from the tables have been plotted for the basic confluent-flow configuration in figure 28. In the bypass duct the flow velocity was reasonably uniform across the station-13.2 annular area. At the mixing plane both the core and bypass flows can be recognized easily. The bypass flow had diffused somewhat at both the inner and outer walls, but the main body of the flow had about the same velocity as that at station 13.2. The core flow had a large velocity deficit at its center, probably caused

by lower energy flow entering the nozzle from the turbine hub area at this speed, as well as by flow losses over the nozzle centerbody. At station 18 both flows had expanded to greater velocity. They probably had begun to mix because the velocity gradients have begun to disappear; however, the percentage of mixing was not computed.

Tables IX to XI show that an appreciable stream static-pressure gradient existed in the mixing plane. The magnitude of the gradient is shown in figure 29, in which the corrected static pressure is shown as a function of the duct radius in the mixing plane. The data are for the basic confluent-flow configuration at two corrected fan speeds. In this figure, the solid lines denote stream static pressure measured during traverses, and the symbols represent such measurements from fixed instrumentation. The static pressure increased from the centerline to the bypass duct wall. Most of the variation occurred in the core stream, and the increase was greater at high fan speed.

Wall static pressures were measured at several stations on the exhaust nozzle wall out to the exit. As part of the study of the confluent-flow systems, the stream static-pressure variation along the length of the exhaust nozzle was computed by the method given in reference 7. In this method, the core and bypass flows are treated as unmixed one-dimensional isentropic confluent flows in which the static pressure is uniform in planes normal to the streamlines. These planes were assumed to be normal to the nozzle axis for the computations shown herein. As shown in figure 29, the condition of uniform static pressure was not met exactly, especially in the core flow at high speeds. For the computations, the effective areas, flow rates, total pressures, and total temperatures measured in performance tests of the same configurations were used.

Results of the theoretical computations are compared with the experimental data in figure 30 for two configurations and two fan speeds. The theoretical stream static pressures compared reasonably well with the measured wall static pressures and were always less than the wall pressures, as expected for the converging passage. In the figure, experimental data and computed pressures also are shown for the bypass-flow duct upstream (negative downstream distance) of the mixing plane. The pressures were computed from isentropic one-dimensional flow relations and the flow coefficient at station 16. Agreement between the computed and measured pressures was not very good, probably because the flow coefficient was changing in the upstream duct.

#### External-Flow Surveys

External-flow surveys were made with the super-rake for some of the confluent-flow configurations. These data are shown in tables XII and XIII and in figures 31 and 32. An index of the tabulated data is as follows:

Confluent-flow configuration	Table	Data-plane distance from exit, cm	Approximate fan speed, rpm
Basic (C-1)	XII(a), (b), (c)	62, 152, 305	3800
	XII(d), (d), (f)	62, 152, 305	4580
	XII(g), (h), (i)	62, 152, 305	5700
	XII(j), (k)	152, 305	7210
Larger exhaust nozzle (C-5)	XIII(a), (b), (c)	152	4580, 6470, 7580

Typical jet-plume velocity data from the tables, along with data previously shown for station 18, are plotted in figure 31. The results show that the jet began to mix and dissipate soon after it left the nozzle. At 3 meters (10 ft) downstream, the high-velocity core remained, but the rest of the jet had spread considerably. The jet plume appeared to be asymmetric, or skewed to the engine centerline. This result appeared consistently in the external-flow survey data from this engine, but the reason is not known.

Typical super-rake data, in normalized form, are shown in figure 32 for a station 152 centimeters (5 ft) aft of the exhaust nozzle in the basic confluent-flow configuration. This figure shows that the skewed velocity pattern noted in the previous figure is related to the total-pressure, stream-static-pressure, and total-temperature gradients, all of which are asymmetric in the measurement plane. Other than asymmetry, the gradients seem to be of normal shape and expected magnitude for this type of jet exhaust.

#### SUMMARY OF RESULTS

The Lycoming YF-102 turbofan engine performed satisfactorily with each of the seven exhaust-system configurations tested. The three separate-flow systems were the basic, the smaller-core-nozzle, and the smaller-fan-nozzle configurations. The four confluent-flow configurations were the basic, the shorter-core-nozzle, and the smaller-core-nozzle configurations. The most important results of the test program are as follows:

1. An engine-synthesis computer program, supplied by Lycoming, provided good estimates of the engine performance and thrust at maximum performance rating for each configuration tested. Inputs necessary for the program include bypass-duct pressure loss (for confluent-flow configurations) and effective flow areas and/or exhaust-system performance coefficients. The largest difference between measured and estimated thrust, 900 newtons (200 lb), occurred for the basic separate-flow configuration near

maximum power. Performance data for all the configurations tested are given in comprehensive tables.

2. Two core nozzles for the confluent-flow systems, the basic nozzle and a shorter nozzle of significantly different design, were tested. Both gave satisfactory internal performance, based on wall static-pressure measurements and overall engine performance.

3. Internal-flow surveys were made, for some of the confluent-flow configurations, in the bypass-flow duct and in the exhaust nozzle. No unusual results were noted. The wall pressures in the nozzle were estimated satisfactorily by compound compressible flow computations. For these computations the flow model is based on the assumption of one-dimensional isentropic flow in both the core and bypass streams, with no mixing.

4. External-flow surveys were made, for some of the confluent-flow configurations, with a large fixed rake. The rake data showed that the jet plume was asymmetric - or skewed to the engine centerline - but otherwise showed expected pressure, temperature, and velocity gradients.

769-02.

## APPENDIX - SYMBOLS<sup>1</sup>

A	geometric flow area (temperature corrected for core nozzles), $\text{cm}^2$ ( $\text{in}^2$ )
BARO	ambient atmospheric pressure, $\text{N}/\text{cm}^2$ ( $\text{lb}/\text{in}^2$ )
CAEXIT	for confluent-flow configurations, the sum of the theoretical area required for station-16 flow when it has expanded isentropically to BARO, plus the theoretical area required for station-6 flow when it has expanded to BARO, all divided by A18, dimensionless
CDENG	core-nozzle discharge coefficient for separate-flow configurations,
	$\frac{W_8}{BARO(A_8)} \sqrt{\frac{2\gamma g}{R(\gamma - 1)(TT_8)} \left[ (H_8)^{(\gamma-1)/\gamma} - 1 \right] (H_8)^{(\gamma-1)/\gamma}}, \text{ dimensionless}$
CDFAN	fan-nozzle discharge coefficient for separate-flow configurations,
	$\frac{W_{13.2}}{BARO(A_{18})} \sqrt{\frac{2\gamma g}{R(\gamma - 1)(TT_{13.2})} \left[ (H_{18})^{(\gamma-1)/\gamma} - 1 \right] (H_8)^{(\gamma-1)/\gamma}},$ dimensionless
CFDUCT	flow coefficient for bypass-flow duct at mixing plane for confluent-flow configurations,
	$\frac{W_{13.2}}{PS_{16}(A_{16})} \sqrt{\frac{2\gamma g}{R(\gamma - 1)(TT_{13.2})} \left[ \left( \frac{PT_{16}}{PS_{16}} \right)^{(\gamma-1)/\gamma} - 1 \right] \left( \frac{PT_{16}}{PS_{16}} \right)^{(\gamma-1)/\gamma}},$ dimensionless
CFENG	core-nozzle flow coefficient for confluent-flow configurations,
	$\frac{W_6}{PS_6(A_6)} \sqrt{\frac{2\gamma g}{R(\gamma - 1)(TT_5)} \left[ \left( \frac{PT_5}{PS_6} \right)^{(\gamma-1)/\gamma} - 1 \right] \left( \frac{PT_5}{PS_6} \right)^{(\gamma-1)/\gamma}}, \text{ dimensionless}$
CVENG	core-nozzle velocity coefficient for separate-flow configurations, dimensionless. (For these tests, CVENG was interpolated from the following: $PT_5/PS_8 = 1.0, 1.2, 1.4$ ; $CVENG = 0.970, 0.976, 0.981$ .)
CVEXIT	exhaust-nozzle velocity coefficient for confluent-flow configurations, $gFG / [W_{13.2}(VIDFAN) + W_6(VIDENG)]$ , dimensionless

<sup>1</sup>When numbers follow the symbols A, PS, PT, PW, TT, W,  $\delta$ , and  $\theta$ , the numbers refer to stations.

CVFAN	fan-nozzle velocity coefficient for separate-flow configurations, $g[(FG) - (FGENG)]/W13.2(VIDFAN)$ , dimensionless
FG	gross thrust, $FM + (Inlet momentum from headwind, if any)$ , N (lb)
FGENG	core-nozzle gross thrust for separate-flow configurations,
	$\frac{W8(CVENG)}{g} \sqrt{\frac{2gR(TT8)}{\gamma - 1} \left[ 1 - \left( \frac{PS8}{PT8} \right)^{\gamma-1} \right] + (PS8 - BARO)A8}, \text{ N (lb)}$
FGK1	corrected gross thrust, $FG/\delta 1$ , N (lb)
FM	measured thrust, N (lb)
FPR	fan pressure ratio, $PT13.2/PT12$ , dimensionless. (For these tests, assume that $PT12 = PT1 = PT0$ .)
FTR	fan temperature ratio, $TT13.2/TT12$ , dimensionless. (For these tests, assume that $TT12 = TT1 = TT0$ .)
g	acceleration due to gravity, $\text{cm/sec}^2$ ( $\text{ft/sec}^2$ ). (For these tests, $g = 980.7 \text{ cm/sec}^2$ ( $32.174 \text{ ft/sec}^2$ )).
HCPR	core-compressor pressure ratio, $PT3/PT2.1$ , dimensionless
H6	core-nozzle pressure ratio for confluent-flow configurations, $PT5/BARO$ , dimensionless
H8	core-nozzle pressure ratio for separate-flow configurations, $PT5/BAE.O$ , dimensionless
H16	bypass-flow pressure ratio for confluent-flow configurations, $PT16/BARO$ , dimensionless
LCPR	supercharger pressure ratio, $PT2.1/PT1$ , dimensionless
NF	fan speed, rpm
NFK1	fan speed corrected to engine inlet conditions, $NF/\sqrt{\theta 1}$ , rpm
NG	core-compressor speed, rpm
NGK1	core-compressor speed corrected to engine inlet conditions, $NG\sqrt{\theta 1}$ , rpm
NGK2.1	core-compressor speed corrected to compressor inlet conditions, $NG\sqrt{\theta 2.1}$ , rpm
PS	static pressure, $\text{N/cm}^2$ ( $\text{lb/in}^2$ )

PS6	core-nozzle exhaust pressure for confluent-flow configurations, N/cm <sup>2</sup> (lb/in <sup>2</sup> ). (For these tests, PS6 was measured by the average of exit-plane wall static and lip static instrumentation.)
PS8	core-nozzle exhaust pressure for separate-flow configurations, N/cm <sup>2</sup> (lb/in <sup>2</sup> ). (For these tests, PS8 was measured by the average of exit-plane wall static and lip static instrumentation.)
PS8K1	core-nozzle exhaust pressure for separate-flow configurations corrected to engine inlet conditions, PS8/δ1, N/cm <sup>2</sup> (lb/in <sup>2</sup> )
PS16	mixing-plane static pressure for confluent-flow configurations, N/cm <sup>2</sup> (lb/in <sup>2</sup> ). (For these tests, PS16 = [3(PW16) + PS6]/4, arbitrarily.)
PS16K1	mixing-plane static pressure for confluent-flow configurations, corrected to engine inlet conditions, PS16/δ1, N/cm <sup>2</sup> (lb/in <sup>2</sup> )
PT	total pressure, N/cm <sup>2</sup> (lb/in <sup>2</sup> )
PW	wall static pressure, N/cm <sup>2</sup> (lb/in <sup>2</sup> )
R	gas constant, evaluated at appropriate temperature and gas composition, J/g K (ft/ <sup>0</sup> R). (For these tests, R = 0.2871 J/g K (53.35 ft/ <sup>0</sup> R) for air near ambient temperature.)
TT	total temperature, K ( <sup>0</sup> R). (For these tests, assume TT1 = TT0.)
T4.1K1	measured gas temperature corrected to engine inlet conditions, TT4.1/(θ1) <sup>1.022</sup> , K ( <sup>0</sup> R)
VIDENG	core-nozzle exhaust velocity if flow expanded isentropically to BARO, m/sec (ft/sec). (For confluent-flow configurations,
	$\text{VIDENG} = \sqrt{\frac{2\gamma g R (TT5)}{\gamma - 1} \left[ 1 - \left( \frac{1}{H6} \right)^{(\gamma-1)/\gamma} \right]}$
	For separate-flow configurations, replace H6 with H8.)
VIDFAN	bypass-flow exhaust velocity if flow expanded isentropically to BARO, m/sec (ft/sec). (For confluent-flow configurations,
	$\text{VIDFAN} = \sqrt{\frac{2\gamma g R (TT13.2)}{\gamma - 1} \left[ 1 - \left( \frac{1}{H16} \right)^{(\gamma-1)/\gamma} \right]}$
	For separate-flow configurations, replace H16 with PT13.2/BARO.)
W	gas flow rate, kg/sec (lb/sec)

WFUEL	fuel flow rate, g/sec (lb/hr)
WFUELK1	fuel flow rate corrected to engine inlet conditions, $WFUEL/\delta_1 \sqrt{\theta_1}$ , g/sec (lb/hr)
W1K1	inlet airflow corrected to engine inlet conditions, $W_1(\sqrt{\theta_1})/\delta_1$ , kg/sec (lb/sec)
W2.1K1	core airflow corrected to engine inlet conditions, $W_{2.1}(\sqrt{\theta_1})/\delta_1$ , kg/sec (lb/sec)
W2.1K2.1	core airflow corrected to core-compressor inlet conditions, $W_{2.1}(\sqrt{\theta_{2.1}})/\delta_{2.1}$ , kg/sec (lb/sec)
W13.2	bypass flow rate, $W_1 - W_{2.1}$ , kg/sec (lb/sec)
$\gamma$	ratio of specific heats, evaluated at appropriate temperature and gas composition, dimensionless. (For these tests, $\gamma = 1.4$ for air near ambient temperature.)
$\hat{o}$	ratio of pressure to standard-day pressure, dimensionless. (For these tests, $\delta_1 = \hat{o}_0 = PT/10.132 \text{ N/cm}^2$ ( $PT/14.696 \text{ lb/in}^2$ )).
$\theta$	ratio of total temperature to standard-day temperature, dimensionless. (For these tests, $\theta_1 = \theta_0 = TT/288.2 \text{ K}$ ( $TT/518.7^\circ \text{ R}$ )).

16 Abstract <p>The performance of a Lycoming YF-102 turbofan engine was measured in an outdoor test stand with a bellmouth inlet and seven exhaust-system configurations. The configurations consisted of three separate-flow systems of various fan and core nozzle sizes and four confluent-flow systems of various nozzle sizes and shapes. A Lycoming computer program provided good estimates of the engine performance and of thrust at maximum rating for each exhaust configuration. The internal performance of two different-shaped core nozzles for confluent-flow configurations was determined to be satisfactory. Pressure and temperature surveys were made with a traversing probe in the exhaust-nozzle flow for some confluent-flow configurations. The survey data at the mixing plane, plus the measured flow rates, were used to calculate the static-pressure variation along the exhaust-nozzle length. The computed pressures compared well with experimental wall static-pressure data. External-flow surveys were made, for some confluent-flow configurations, with a large fixed rake at various locations in the exhaust plume.</p>
